GeneGeneInteR vignette Statistical analysis of the interaction between a pair of genes.

Mathieu Emily and Magalie Houée-Bigot

April 25, 2023

This vignette presents the technical details of the statistical procedure implemented in the package. Readers that would like to have a global overview of the main functions and tools proposed in the package are encouraged to read the vignette **VignetteGeneGeneInteR Introduction**.

1 Introduction

In this vignette we consider statistical procedures to test for the interaction between two genes in susceptibility with a binary phenotype, typically a case/control disease status. Let $Y \in \{0, 1\}$ be the phenotype, where Y = 0stands for a control and Y = 1 a case, and X_1 and X_2 be the two genes for which the interaction is tested.

Let consider a sample of n individuals with n_c controls and n_d cases $(n_c+n_d=n)$ and $\mathbf{Y} = [y_1, \ldots, y_n]'$ the vector of the observed binary phenotypes. Each gene is a collection of respectively m_1 and m_2 SNPs. The observed genotypes for gene X_1 can be represented by a $n \times m_1$ matrix: $\mathbf{X}_1 = [x_{ij}^1]_{i \in 1...n; j \in 1...m_1}$ where $x_{ij}^1 \in \{0; 1; 2\}$ is the number of copies of the minor allele for SNP j carried by individual i. A similar representation is used for gene X_2 where \mathbf{X}_2 is a $n \times m_2$ matrix. Let us further introduce \mathbf{X}_1^c and \mathbf{X}_2^c the matrices of observed genotypes among controls for gene 1 and 2 and \mathbf{X}_1^d and \mathbf{X}_2^d among cases for both genes. Thus \mathbf{X}_1^c is a $n_c \times m_1$ matrix, \mathbf{X}_1^d a $n_d \times m_1$ matrix, \mathbf{X}_2^c a $n_c \times m_2$ matrix and \mathbf{X}_2^d a $n_d \times m_2$ matrix. A general setup of the observed values can be presented as follows:

$$\mathbf{Y} = \begin{bmatrix} y_1 \\ \vdots \\ y_{n_c} \\ y_{n_c+1} \\ \vdots \\ y_{n_c+n_d} \end{bmatrix} \mathbf{X}_1 = \begin{bmatrix} \mathbf{X}_1^{\mathbf{c}} \\ \mathbf{X}_1^{\mathbf{c}} \\ \mathbf{X}_1^{\mathbf{d}} \end{bmatrix} = \begin{bmatrix} x_{11}^{\mathbf{1}} & \dots & x_{1m_1}^{\mathbf{1}} \\ \vdots & \ddots & \vdots \\ x_{n_c1}^{\mathbf{1}} & \dots & x_{n_cm_1}^{\mathbf{1}} \\ x_{(n_c+1)1}^{\mathbf{1}} & \dots & x_{(n_c+1)m_1}^{\mathbf{1}} \\ \vdots & \ddots & \vdots \\ x_{(n_c+n_d)1}^{\mathbf{1}} & \dots & x_{(n_c+n_d)m_1}^{\mathbf{1}} \end{bmatrix} \mathbf{X}_2 = \begin{bmatrix} \mathbf{X}_2^{\mathbf{c}} \\ \mathbf{X}_2^{\mathbf{c}} \\ \mathbf{X}_2^{\mathbf{c}} \end{bmatrix} = \begin{bmatrix} x_{11}^2 & \dots & x_{1m_2}^2 \\ \vdots & \ddots & \vdots \\ x_{n_c1}^2 & \dots & x_{n_cm_1}^2 \\ x_{(n_c+1)1}^2 & \dots & x_{(n_c+1)m_1}^2 \\ \vdots & \ddots & \vdots \\ x_{(n_c+n_d)1}^2 & \dots & x_{(n_c+n_d)m_1}^2 \end{bmatrix}$$

In our package we proposed 10 methods for testing interaction at the gene level. These 10 methods are all based on three main parameters: Y, a numeric or factor vector with exactly two distinct values, G1 and G2 two SnpMatrix objects as proposed by the R Bioconductor package snpStats. Our implementation is illustrated by the dataset gene.pair provided with the GeneGeneInteR package and summarized in the following command lines:

> library("GeneGeneInteR")
> data("gene.pair")
> head(gene.pair\$Y)

[1] HealthControl HealthControl HealthControl HealthControl HealthControl Levels: HealthControl RheumatoidArthritis

> gene.pair\$G1

```
A SnpMatrix with 453 rows and 8 columns
Row names: Id1 ... Id453
Col names: rs1491710 ... rs2298849
> gene.pair$G2
A SnpMatrix with 453 rows and 4 columns
Row names: Id1 ... Id453
Col names: rs2057094 ... rs1005753
```

The 10 methods implemented in our package can be divided into two main families: 6 methods based on a multidimensional modeling of the interaction at the gene level and 4 methods that combine interaction tests at the SNP level into a single test at the gene level.

2 Multidimensional methods at the gene level

In the **GeneGeneInteR** package, 6 multidimensional methods have been implemented that are based on:

- Principal Components Analysis PCA.test function,
- Canonical Correlation Analysis CCA.test function,
- Kernel Canonical Correlation Analysis KCCA.test function,
- Composite Linkage Disequilibrium CLD.test function,
- Partial Least Square Path Modeling PLSPM.test function,
- Gene-Based Information Gain Method GBIGM.test function.

In the remainder of this section, technical and practical details are given regarding these 6 methods.

2.1 PCA-based

In the PCA-based method, a likelihood ratio test is performed to compare the model \mathcal{M}_{Inter} to the model \mathcal{M}_{No} , where \mathcal{M}_{Inter} is defined by:

$$\operatorname{logit}\left(\mathbb{P}\left[Y=1|PC_{X_{1}}^{1}\dots PC_{X_{1}}^{n_{1}}, PC_{X_{2}}^{1}\dots PC_{X_{2}}^{n_{2}}\right]\right) = \beta_{0} + \sum_{i=1}^{n_{1}} PC_{X_{1}}^{i} + \sum_{j=1}^{n_{2}} PC_{X_{2}}^{j} + \sum_{i=1}^{n_{1}} \sum_{i=2}^{n_{2}} PC_{X_{1}}^{i} PC_{X_{2}}^{j}$$

and \mathcal{M}_{No} by:

logit
$$\left(\mathbb{P}\left[Y=1|PC_{X_1}^1\dots PC_{X_1}^{n_1}, PC_{X_2}^1\dots PC_{X_2}^{n_2}\right]\right) = \beta_0 + \sum_{i=1}^{n_1} PC_{X_1}^i + \sum_{j=1}^{n_2} PC_{X_2}^j$$

In models \mathcal{M}_{Inter} and \mathcal{M}_{No} , $PC_{X_1}^i$ and $PC_{X_2}^j$ are the i^{th} principal component of \mathbf{X}_1 and the j^{th} principal component of \mathbf{X}_2 . The number of principal components, n_1 and n_2 , kept in the interaction test is determined by the percentage of inertia retrieved by the PCA. Such a percentage is defined by the user and corresponds to the threshold parameter.

In our package, two distinct Principal Component decomposition are provided by the functions PCA.test via the argument method. With method="Std", dataset is standardized using variables' standard deviation while with method="GenFreq", dataset is standardized using standard deviation under Hardy-Weinberg equilibrium, as proposed in the snpStats package.

When the percentage of inertia asked by the user is high, the number of PCs can be important and fitting logistic models \mathcal{M}_{Inter} and \mathcal{M}_{No} is likely to fail. In that case, the number of PCs in each gene is iteratively reduced until convergence of the glm function for fitting models \mathcal{M}_{Inter} and \mathcal{M}_{No} .

The following lines provide an example of the PCA.test function:

```
> PCA.test(Y=gene.pair$Y, G1=gene.pair$G1, G2=gene.pair$G2,threshold=0.7,
+ method="GenFreq")
```

Gene-based interaction based on Principal Component Analysis - GenFreq

Gene-based interaction based on Principal Component Analysis - Std

2.2 Canonical Correlation Analysis (CCA)

The CCA test is based on a Wald-type statistic defined as follows (see [Peng et al., 2010] for details):

$$U_{CCA} = \frac{z_d - z_c}{\sqrt{\mathbb{V}(z_d) + \mathbb{V}(z_c)}}$$

where $z_d = \frac{1}{2} (\log(1 + r_d) - \log(1 - r_d))$ and $z_c = \frac{1}{2} (\log(1 + r_c) - \log(1 - r_c))$ with r_d the maximum canonical correlation coefficient between $\mathbf{X_1^d}$ and $\mathbf{X_2^d}$ and r_c the maximum canonical correlation coefficient between $\mathbf{X_1^d}$ and $\mathbf{X_2^d}$ and r_c the maximum canonical correlation coefficient between $\mathbf{X_1^c}$ and $\mathbf{X_2^c}$ computed for controls (Y = 0). As suggested by [Peng et al., 2010], the sampled variances $\mathbb{V}(z_d)$ and $\mathbb{V}(z_c)$ were evaluated by applying a bootstrapping method. The number of bootstrap sample used to estimate $\mathbb{V}(z_d)$ and $\mathbb{V}(z_c)$ is determined by the **n**.**boot** argument. P-value is then obtained by noting that under the null hypothesis $U_{CCA} \sim \mathcal{N}(0, 1)$.

CCA based gene-gene interaction is implemented in the CCA.test function and mainly depends on the cancor function from the Stats package [R Core Team, 2016].

```
R> set.seed(1234)
```

> CCA.test(Y=gene.pair\$Y, G1=gene.pair\$G1, G2=gene.pair\$G2,n.boot=500)

Gene-based interaction based on Canonical Correspondance Analysis

2.3 Kernel Canonical Correlation Analysis (KCCA)

The KCCA based test provides a generalization of CCA test to detect non-linear co-association between X_1 and X_2 [Yuan et al., 2012, Larson and Schaid, 2013] and is based on the following Wald-type statistic:

$$U_{KCCA} = \frac{kz_d - kz_c}{\sqrt{\mathbb{V}(kz_d) + \mathbb{V}(kz_c)}}$$

where $kz_d = \frac{1}{2} (\log(1 + kr_d) - \log(1 - kr_d))$ and $kz_c = \frac{1}{2} (\log(1 + kr_c) - \log(1 - kr_c))$ with kr_d the maximum kernel canonical correlation coefficient between $\mathbf{X_1^d}$ and $\mathbf{X_2^d}$ and kr_c the maximum kernel canonical correlation coefficient between $\mathbf{X_1^d}$ and $\mathbf{X_2^d}$.

Similar to the CCA test, $\mathbb{V}(kz_d)$ and $\mathbb{V}(kz_c)$ are estimated using bootstrap techniques [Yuan et al., 2012, Larson and Schaid, 2013] and the p-value is obtained using the standard gaussian distribution of U_{KCCA} under the null hypothesis. Since the performance of kernel methods strongly relates to the choice of kernel functions, the default is the Radial Basis kernel Function (RBF) owing to its flexibility in parameter specification. However, other kernel functions, such as linear, polynomial or spline kernels, can be used. Thus, in addition to the three arguments Y, G1 and G2, our implementation of the KCCA test proposes two optional arguments: n.boot that determines the number of bootstrap samples and kernel that provides the kernel function to be used. This kernel parameter is character string matching one of the kernel name provided by the kernlab package [Karatzoglou et al., 2004] such as "rbfdot", "polydot", "tanhdot", "vanilladot", "laplacedot", "besseldot", "anovadot", "splinedot". Specific arguments, sigma, degree, scale, offsetand order, can also be passed to the kcca.test function in order to parameterized the kernel used in the analysis.

KCCA based gene-gene interaction test is implemented in the KCCA.test function and mainly depends on the kcca function from the kernlab package [Karatzoglou et al., 2004].

```
> set.seed(1234)
> KCCA.test(Y=gene.pair$Y, G1=gene.pair$G1,G2=gene.pair$G2,

sample estimates:
       z0
                 z_1
 4.161048 -4.251702
```

2.4 Partial Least Square Path Modeling (PLSPM)

The PLSPM testing has been introduced by [Zhang et al., 2013] and is based on the Wald-like statistic:

$$U_{PLSPM} = \frac{\beta_d - \beta_c}{\sqrt{\mathbb{V}(\beta_d - \beta_c)}}$$

where β_d (resp. β_c) is the path coefficient between $\mathbf{X_1^d}$ and $\mathbf{X_2^d}$ (resp. $\mathbf{X_1^c}$ and $\mathbf{X_2^c}$). As quoted by [Zhang et al., 2013], the distribution of U_{PLSPM} is unknown and significance can be tested with bootstrapping method.

PLSPM based gene-gene interaction test is implemented in the PLSPM.test function and mainly depends on the plspm function from the plspm package [Sanchez et al., 2015].

```
> set.seed(1234)
> PLSPM.test(Y=gene.pair$Y, G1=gene.pair$G1,G2=gene.pair$G2,n.perm=1000)
```

Gene-based interaction based on Partial Least Squares Path Modeling

2.5 Composite Linkage Disequilibrium (CLD)

The CLD method, proposed in [Rajapakse et al., 2012] is based on the normalized quadratic distance (NQD) and is defined as

$$\delta^2 = \operatorname{tr.}\left((\tilde{D} - \tilde{C}) W^{-1} (\tilde{D} - \tilde{C}) W^{-1} \right)$$

where \tilde{D} , \tilde{C} and W are three $(m_1 + m_2) \times (m_1 + m_2)$ matrices of the covariance between the whole set of SNPs that combines SNPs from both genes. More precisely, \tilde{D} and \tilde{C} are defined as follows:

$$\tilde{D} = \begin{bmatrix} W_{11} & D_{12} \\ D_{21} & W_{22} \end{bmatrix} \qquad \tilde{C} = \begin{bmatrix} W_{11} & C_{12} \\ C_{21} & W_{22} \end{bmatrix}$$

where W_{11} (resp. W_{22}) is the pooled estimate of the covariance matrix for \mathbf{X}_1 (resp. \mathbf{X}_2 , $D_{12}(=D'_{21})$ and $C_{12}(=C'_{21})$ are the sample covariance matrix between the two genes estimated from $(\mathbf{X}_1^d, \mathbf{X}_2^d)$ and $(\mathbf{X}_1^c, \mathbf{X}_2^c)$ respectively. In more details, the sample covariance matrices in cases, denoted by D, and in controls, denoted by C, can be partitioned in 4 blocks as follows:

$$D = \operatorname{Cov}\left(\mathbf{X_{1}^{d}, X_{2}^{d}}\right) = \begin{bmatrix} D_{11} & D_{12} \\ D_{21} & D_{22} \end{bmatrix} \qquad C = \operatorname{Cov}\left(\mathbf{X_{1}^{c}, X_{2}^{c}}\right) = \begin{bmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{bmatrix}$$

The pooled estimate of the covariance matrix, W, can thus been obtained by:

$$W = \frac{n_c C + n_d D}{n_c + n_d} = \begin{bmatrix} W_{11} & W_{12} \\ W_{21} & W_{22} \end{bmatrix}$$

Since the distribution of δ^2 is not known under the null hypothesis, significance testing is performed using permutation tests, as proposed by [Rajapakse et al., 2012]. Such a test has been implemented in our package in the CLD.test function where the number of permutations is determined by the argument n.perm.

```
> set.seed(1234)
```

```
> CLD.test(Y=gene.pair$Y, G1=gene.pair$G1,G2=gene.pair$G2,n.perm=2000)
```

Gene-based interaction based on Composite Linkage Disequilibrium

2.6 Gene-Based Information Gain Method (GBIGM)

Introduced by [Li et al., 2015], the GBIGM method is based on the information gain rate $\Delta R_{1,2}$. $\Delta R_{1,2}$ is defined as follows:

$$\Delta R_{1,2} = \frac{\min(H_1, H_2) - H_{1,2}}{\min(H_1, H_2)}$$

where H_1 , H_2 , $H_{1,2}$ are the conditional entropies, given the **Y**, of **X**₁, **X**₂ and the pooled SNP set (**X**₁, **X**₂) respectively. Assuming that H(.) is the classical entropy function, we have:

$$H_{1} = H(\mathbf{Y}, \mathbf{X}_{1}) - H(\mathbf{X}_{1})$$

$$H_{2} = H(\mathbf{Y}, \mathbf{X}_{2}) - H(\mathbf{X}_{2})$$

$$H_{1,2} = H(\mathbf{Y}, \mathbf{X}_{1}, \mathbf{X}_{2}) - H(\mathbf{X}_{1}, \mathbf{X}_{2})$$

Since the distribution of $\Delta R_{1,2}$ is unknown, the significance testing is performed by permutations as suggested by [Li et al., 2015]. The GBIGM method has been implemented in the GBIGM.test function and the number of permutations is defined by the argument n.perm.

```
> set.seed(1234)
> GBIGM.test(Y=gene.pair$Y, G1=gene.pair$G1,G2=gene.pair$G2,n.perm=2000)
```

3 From SNP-SNP interaction to Gene-Gene interaction testing

This section provides details of the four statistical methods that proposes a gene-based test from SNP-based tests [Emily, 2016]. Rather than considering multiple SNPs in both gene as part of a joint model, these methods aim at aggregating p-values obtained at the SNP level into a single p-value at a gene level.

Interaction testing at the SNP level

Let consider a pair of SNPs, $(X_{1,j}, X_{2,k})$ where $X_{1,j}$ is the j^{th} SNP of gene X_1 and $X_{2,k}$ the k^{th} SNP of gene X_2 $(1 \le j \le m_1 \text{ and } 1 \le k \le m_2)$. To test for interaction at the SNP level, we used the following Wald statistic:

$$W_{jk} = \frac{\widehat{\beta_3^{j,k}}}{\sigma\left(\widehat{\beta_3^{j,k}}\right)}$$

where $\widehat{\beta_{3}^{j,k}}$ is an estimate of the interaction coefficient $\beta_{3}^{j,k}$ of the following logistic model:

$$\log\left(\frac{\mathbb{P}[Y=1|X_{1,j}=x_1, X_{2,k}=x_2]}{1-\mathbb{P}[Y=1|X_{1,j}=x_1, X_{2,k}=x_2]}\right) = \beta_0^{j,k} + \beta_1^{j,k}x_1 + \beta_2^{j,k}x_2 + \beta_3^{j,k}x_1x_2$$

 $\widehat{\beta_3^{j,k}}$ is obtained by maximizing the likelihood function on the observed data $\mathbf{Y}, \mathbf{X_1}$ and $\mathbf{X_2}$ while σ $\beta_3^{j,k}$ is

calculating by inverting the Hessian of the likelihood. Since the solution of the maximization of the likelihood function does not have a closed form, we compute W_{ik} according to the iteratively reweighted least squares algorithm proposed in the glm function of the stats package [R Core Team, 2016].

To combine the statistics W_{jk} into a single test, [Ma et al., 2013] proposed four methods that all account for covariance matrix $\Sigma = [\sigma_{(j,k),(j',k')}]_{j=1...m_1;k=1...m_2}$, a $(m_1 \times m_2) \times (m_1 \times m_2)$ symmetric matrix where $j'=1...m_1;k'=1...m_2$ $\sigma_{(j,k),(j',k')} = Cov(W_{jk}, W_{j',k'})$. As proposed by [Emily, 2016], the covariance between W_{jk} and $W_{j',k'}$ is

estimated by:

$$\widehat{\sigma_{(j,k),(j',k')}} = r_{j,j'} r_{k,k'}$$

where $r_{j,j'} = \frac{p_{jj'} - p_j p_{j'}}{\sqrt{p_j (1 - p_j) p_{j'} (1 - p_{j'})}}$ is the widely used correlation measure between SNP j and SNP j', given that p_j and $p_{j'}$ are the respective allelic frequencies and $p_{jj'}$ is the joint allelic frequency [Hill and Robertson, 1968].

In the remainder of this section, the four methods: minP (function minP.test, GATES (function gates.test), tTS (function tTS.test) and tProd (function tProd.test) are detailed.

3.1minP

The minP test is based on the minimum p-value that is often used to combine p-values of association (see [Connecly and Boehnke, 2007]). Let $W_{\text{max}} = \max |W_{11}|, \ldots, |W_{m_1,m_2}|$ be the maximum of the absolute observed statistics. The minP is then defined by:

$$\min \mathbf{P} = 1 - \mathbb{P}\Big[\max(|Z_1|, |Z_2|, \dots, |Z_{m_1 m_2}|) < W_{\max}\Big].$$
(1)

where $\mathbb{Z} = (Z_1, Z_2, \dots, Z_{m_1 m_2})$ is a random vector that follows a multivariate normal distribution $\mathbb{Z} \sim \mathcal{N}(\mathbf{0}, \Sigma)$.

The computation of Equation (1) requires the calculation of the probability distribution of a multivariate normal random variable. For that purpose, we used the pmvnorm function from the R package mvtnorm [Genz and Bretz, 2009].

```
> set.seed(1234)
> minP.test(Y=gene.pair$Y, G1=gene.pair$G1,G2=gene.pair$G2)
```

Gene-based interaction based on minP method

```

alternative hypothesis: true Wmax is greater than O
sample estimates:
       Wmax
0.009924148
```

3.2GATES

The GATES procedure, proposed by [Li et al., 2011], is an extension of the Simes procedure used to assess the gene level association significance. Let $p_{(1)}, \ldots, p_{(m_1m_2)}$ be the ascending SNP-SNP interaction $m_1 \times m_2$ p-values, GATES p-value is then defined by

0.01394543

$$p_{GATES} = \min\left(\frac{mep_{(1)}}{me_{(1)}}, \frac{mep_{(2)}}{me_{(2)}}, \dots, \frac{mep_{(m_1m_2)}}{me_{(m_1m_2)}}\right)$$

where m_e is the number of effective tests among the $m_1 \times m_2$ tests and $m_{e(i)}$ the number of effective tests among the *i* most significative tests associated with the lowest order p-values $p_{(1)}, \ldots, p_{(i)}$. The number of effective tests ought to characterize the number of independent tests equivalent to the correlated tests that are really performed and is often used to account for dependence in a multiple testing correction.

Although no formal definition of the number of effective tests has been formulated in the literature, several procedures have been proposed to estimate such number. All methods are based on a transformation of the set of eigenvalues of the SNP covariance matrix assuming that (1) if the SNPs are independent, the number of effective tests is the number of performed, (2) if the absolute value of the correlation between any pair of SNPs is equal to 1, the number of effective tests is 1. In the **GeneGeneInteR** package, four main methods have been implemented and can be chosen by the user with the argument merest: Cheverud-Nyholt method - me.est="ChevNy" [Cheverud, 2001, Nyholt, 2004], Keff method -me.est="Keff" [Moskvina and Schmidt, 2008], Li and Ji method - me.est="Calwey" [Galwey, 2009].

0.01394543
```

3.3 tTS and tProd

tTS and tProd procedures are two truncated tail strength methods that aim at combining signals from all single-SNP p-values less than a predefined cutoff value [Jiang et al., 2011]. Denoting by τ the cutoff value, the two truncated p-values are defined as follows [Zaykin et al., 2002]:

$$\begin{split} tTS &= \frac{1}{m_1 m_2} \sum_{i=1}^{m_1 m_2} \mathbb{I}(p_{(i)} < \tau) \left(1 - p_{(i)} \frac{m_1 m_2 + 1}{i} \right) \\ tProd &= \prod_{i=1}^{m_1 m_2} p_i^{\mathbb{I}(p_i < \tau)} \end{split}$$

where \mathbb{I} is the indicator function.

When p-values are correlated, the null distribution of tTS and tProd are unknown. Following the approach proposed by [Zaykin et al., 2002], a p-value is obtained in the **GeneGeneInteR** package by computing an empirical null distribution using Monte-Carlo (MC) simulations. For each MC iteration, an empirical value for tTS (or tProd) is obtained by simulating a vector of W_{jk} with respect to a multivariate normal distribution with a vector of 0 means and $\hat{\Sigma}$ as covariance matrix. The empirical p-value is calculated as the proportion of simulated statistics larger than the observed statistic on the "true" set of W_{jk} .

tTS and tProd methods have been implemented in the functions tTS.test and tProd.test of the GeneGeneInteR package. Additional to the mandatory Y, G_1 and G_2 arguments, these two functions have two optional arguments: tau and n.sim that control the cutoff value and the number of simulations used to estimate the empirical value respectively. The following coding lines give an example of the tTS.test and tProd.test:

```
> set.seed(1234)
> tTS.test(Y=gene.pair$Y, G1=gene.pair$G1,G2=gene.pair$G2,tau=0.5,n.sim=10000)
        Gene-based interaction based on the Truncated Tail Strength method
      gene.pair$Y and (gene.pair$G1 , gene.pair$G2)
data:
tTS = -0.0099127, tau = 0.5, p-value = 0.5104
alternative hypothesis: less
sample estimates:
         tTS
-0.009912706
> set.seed(1234)
> tProd.test(Y=gene.pair$Y, G1=gene.pair$G1,G2=gene.pair$G2,tau=0.05,n.sim=1000)
        Gene-based interaction based on the Truncated Product method
data: gene.pair$Y and (gene.pair$G1, gene.pair$G2)
tProd = 0.0001384, tau = 0.05, p-value = 0.265
alternative hypothesis: less
sample estimates:
       tProd
